1. Introduction

Health Indicators Series:  
A Resource for Healthy Communities  
April 2011

*Health Indicators* is a series of reports describing community health at the state, regional, and county level. *Health Indicators* supplements the *Eastern North Carolina Health Care Atlas* published by the Center for Health Services Research and Development at East Carolina University. These reports are intended to provide state policy makers, local health departments, hospitals, and community-based health planning groups with a wide range of information useful for diagnosing the health of Eastern North Carolina’s population and its local communities, evaluating the effectiveness of existing services, and envisioning and planning new interventions. The reports in this periodically published series can be used in conjunction with the *County Health Data Book*, produced by the North Carolina Office of Healthy Carolinians, as part of the Community Health Assessment Process. Individual reports in ECU’s Health Indicator Series are custom made for the counties of North Carolina. Reports in this series will describe trends in mortality, including premature mortality for all causes of death, mortality (crude) and age-adjusted mortality for leading causes of death, and measures of race disparities or inequalities in mortality rate.

*Report Series #2* of the series focuses attention on the two overarching goals of *Healthy People 2020*, the national blueprint for health improvement. The first goal is to increase the span and quality of life and the second is to eliminate health disparities. North Carolina’s companion plan, *Healthy Carolinians 2020*, has also embraced these two goals. Using rate comparisons, this report describes the inequalities in mortality among Eastern North Carolina and other regions, and among four demographic groups. Premature mortality, the focus of Report Series #1, is included in the death from all causes section located at the beginning of this report. The measure used to quantify premature mortality is described in more detail in the Methods and Interpretations section.

This report describes the leading contributors to mortality, provides a geographic context, and examines trends and inequalities over a 29-year period (1979-2008), as well as the most recent ten year period (1999 to 2008). The report begins with data highlights, provided as an introduction to the data, rather than a summary of it. Readers are encouraged to draw their own conclusions from the data and pose new questions suggested by what they see. The following section presents both the overall and five leading contributors to mortality for the state by race and gender. In this section, pie charts describe the relative contribution of each of five leading contributors to the overall, general rate. These charts also make regional and demographic comparisons. Making the area of each pie chart equivalent to the rate for the population group helps convey the dimension of disparity across population groups. The next section charts recent trends and disparities in mortality and provides projections to the year 2020. These charts place Eastern North Carolina’s health status in a historical context and provide a glimpse into the future.
The region *Eastern North Carolina* is comprised of 41 counties located in the extreme east of North Carolina and approximates the coastal plain physiographic province of the state. It includes all counties east of I-95. This region is characterized by its rurality, poverty, and some of the highest mortality rates in the nation. The name of the region is abbreviated as ENC41 or ENC. The rest of North Carolina is the remaining 59 counties; abbreviated as RNC59 or RNC.
2. Data Highlights

Trends and Disparities in Mortality in Eastern North Carolina

The following highlights of mortality in the 41 counties of Eastern North Carolina (ENC41) describe current status and trends in the causes of death from major diseases and how they vary across different population groups. The graphs, charts, and tables paint a picture of the region’s health with a broad brush. The study of mortality in populations should include consideration of time and geographic space as well as underlying demographic, political-economic, and socio-cultural conditions. Readers are encouraged to think of these factors as they consider the data presented in this report, formulate their own questions about the causes of mortality, and think about strategies to reduce mortality in the population described.

Current Disparities in Mortality by Geography, Race, and Gender

In 2008, age-adjusted mortality rate for Eastern North Carolina is 873 deaths per 100,000. This rate is 6% higher than the state rate. Within Eastern North Carolina, the non-White rate is 16% higher than the White rate. The non-White male rate is 26% higher than the rate for White males. The non-White female rate is 11% higher than the rate for White females.

The five specific leading causes of mortality in Eastern North Carolina (2008) are:
1. Diseases of Heart
2. Cancer - All Sites
3. Cerebrovascular Disease
4. Chronic Lower Respiratory Diseases
5. Diabetes Mellitus

The five specific leading causes of mortality in Eastern North Carolina by race and gender (2008) are:

Trends in Mortality from All Causes

- ENC’s all-cause mortality rates are increasing and diverging from RNC and NC over the 30-year trend. Over the 10 year trend period, however, ENC, NC, and RNC are decreasing. ENC is not decreasing as quickly as NC and RNC.
- The age-adjusted, all-cause mortality rates for ENC are decreasing over the 30 year period. Over the 10 year period, the trend shows greater decrease, and suggests the ENC rate will converge with the RNC and NC rates. ENC’s rate continues to remain 10% greater than the rate for RNC.
- The non-White male mortality rates remain higher than the other demographic groups but have had the greatest rate of decrease (23%) in the 10-year trend. Convergence of non-White males with White males is suggested in the future.
- The trends for all-cause mortality rates for both non-Whites and Whites are decreasing. The non-White rate is 19% greater than the White rate, but the recent 10 year trend suggests they will converge.
- There is a 45% increase in racial disparity over the 30 year period. Over the recent 10 year period, however, there is a sharp drop in racial disparity, in a moderately reliable trend.

Trends in Premature Mortality from All Causes of Death

- ENC’s premature mortality rate has decreased by 5% over the 10 year period since 1999. However, this trend is diverging slightly from both RNC and NC, whose premature mortality rates decreased by 8% and 7%, respectively.
- The age-adjusted premature mortality rate trend is also decreasing, but remains 23% higher than the RNC rate in 2008.
- The non-White male rates are significantly higher than any other demographic group, but also have the highest rate of decrease (slope of trend). White females have the lowest rate and also the lowest rate of decrease.
- The non-White female fitted rate was 77% greater than that of the White females in 1999, decreasing to 60% greater in 2008.
- A recent decrease in the premature mortality rate for non-White males and leveling of rates for White males suggests a reduction in racial disparity.
- The non-White rate remains about 59% greater than the White rate.

Diseases of the Heart

- ENC’s heart disease mortality rate trend is decreasing but not as quickly as the decrease for RNC and NC, resulting in an increased geographic disparity. In 1999 it was 7% less than RNC; by 2008 it was 15% greater than RNC.
- While ENC’s age-adjusted mortality rate is decreasing at a pace equal to RNC, the ENC rate remains 18% greater than RNC in 2008.
- The non-White male rates remain the highest but convergence with White males is suggested in the future. The non-White female rates remain slightly higher than the White females but are decreasing at a higher rate and suggested to fall below White females in the future.
- While non-White rates remain 13% greater than for Whites, the 10-year trends are both decreasing and convergence is suggested in the future.
- The 30-year trend suggests an increase in racial disparity after an initial reversal of disparity that favored non-Whites. The 10-year trend line for racial disparity is unreliable.

Cancer – Trachea, Bronchus, Lung

- While the 30-year trends for Cancer—TBL indicate that all mortality rates are continuing to increase, the 10-year trend line suggest a slight decrease in all three trends. However, ENC continues to be 9% greater than RNC in 2008 and has divergence from RNC and NC.
In 2008, the age-adjusted rate for ENC is 8% above the RNC rate and 18% above the US rate. During the period 1999-2008, the ENC rates are decreasing at a greater rate, suggesting convergence with RNC and NC in the future.

- The mortality rates for males are decreasing as female rates are increasing. While the non-White male rate remains the highest, it is decreasing at the quickest rate (28%) and is expected to fall below White males.
- The non-White mortality rate (combined males and females) for this cancer is consistently lower than the white rate. Both rates are decreasing over the 10 year period, but the non-White rate is decreasing more quickly.
- The decreasing trend for racial disparity is not reliable.

**Cerebrovascular Disease**

- ENC’s cerebrovascular disease mortality trend line is decreasing and diverging slightly from RNC and NC. In 1999, the ENC rate was 2% greater than RNC compared to 6% greater in 2008.
- While the ENC age-adjusted cerebrovascular disease mortality rate is 9% greater than the rate for the rest of the state, it is decreasing and converging on the RNC and NC rates. Projected to 2010, the Healthy People 2010 goal of less than 48 deaths per 100,000 could be achieved in the region.
- Non-Whites have the highest mortality rate for cerebrovascular disease but the rate continues to decrease and converge with the other demographic groups. The greatest relative improvement in cerebrovascular disease mortality over 10 years is by White males who experienced a 51% decrease. The non-White male rate in 2008 is 75% greater than the rate for White males; the non-White female rate is 43% greater than the rate for White females.
- The cerebrovascular disease mortality rate for non-Whites is decreasing and converging with that of whites but is still 52% greater than Whites in 2008.
- The moderately reliable 10-year trend for racial disparity shows a 46% increase

**Chronic Lower Respiratory Diseases**

- The CLRD mortality rates for ENC are slightly lower than the rates for RNC and NC in 2008, with all 3 trends increasing. Only RNC has a moderately reliable 10-year trend with a 6% increase.
- The 10-year CLRD age-adjusted rate for ENC is decreasing at a similar rate of decline as the US. In 2008, the ENC rate is 5% less than RNC compared to 1999 when the ENC rate was 10% greater than RNC.
- Fitted rates for non-White male and White male mortality have decreased over 10 years by 39% and 22%, respectively. White male rates remain the highest and although decreasing, are diverging from non-White males. The 10-year trend for White females show a 7% increase and the trend for non-White females is unreliable.
- The 10-year White morality rates are greater than non-White rates and the rate of decline is less for Whites, leading to a divergence more favorable to non-Whites.
- There is a 70% decrease in the disparity between White rates and non-White rates in a reliable trend.

**Diabetes Mellitus**

- According to the 10-year trend, all diabetes mellitus mortality rates are decreasing but the rate of decline is less for ENC suggesting a divergence from RNC and NC. In 2008, the rate for ENC is 41% greater than RNC. In 1999 ENC was 26% greater than RNC.
The 10-year trend for age-adjusted diabetes mellitus mortality rates shows a decrease of 13% for ENC as the rates for RNC and NC have fallen below the US rate. In 2008, the ENC age-adjusted diabetes mellitus death rate remains 43% greater than the RNC and 12% greater than the US rate.

The non-White male and non-White female 10-year mortality rate trends are decreasing and converging with those of White males and White females. The annual decrease for the highest group, non-White males, is 2.0%.

Non-White mortality rates decreased over 10 years by 17% but remains 131% greater than Whites in 2008.

There has been a 14% decrease in racial disparity from 1999-2008. The trend in disparity is decreasing at an average of 1.4% per year, with a moderately reliable trend.

### All Other Unintentional Injuries and Adverse Effects

- Mortality from unintentional injuries and adverse effects is increasing in ENC (37% increase over 10 years). The trends for RNC and NC are also increasing, more quickly than ENC.
- The age-adjusted mortality rates for ENC, RNC and NC are also increasing. The rate of increase is higher for NC and RNC than for ENC, but all three increased 30% or more over 10 years.
- 10 year trends for White males and White females are increasing significantly (40% increase for White males, 87% increase for White females). Mortality rates for non-White males decreased 21% over 10 years, and the trend for non-White females is relatively flat.
- White rates have increased 56% over the 10 year period. Non-White rates have dropped below white rates, and are decreasing, in an unreliable trend.
- Between 1999 and 2008, the racial disparity has decreased by 295%, eliminating the unfavorable disparity in relation to whites.

### Alzheimers Disease

- The Alzheimer’s mortality rate for ENC shows a 72% increase over the 10 year period. ENC’s rate of increase was larger than RNC and NC but the rate for ENC still remains 37% less than RNC.
- In 2008, the age-adjusted rate for ENC is 13% below the US rate with a rate of increase comparably similar to both the NC and US rates.
- The mortality rate for females, both White and non-White, is greater than that of non-White and White males in an increasingly divergent 10-year trend.
- The non-White mortality rate for Alzheimer’s remains 10% less than the White mortality rate in 2008 but the 10-year trend suggest convergence in the near future.
- The 10-year trend suggests an increase in disparity that is beginning to favor whites.

### Unintentional Motor Vehicle Injuries

- ENC’s unintentional motor vehicle injury mortality rate is decreasing but is 49% greater than RNC in 2008. Because of its smaller rate of decrease, ENC rates are diverging from the RNC and NC rates.
- The ENC age-adjusted rate is 49% greater than RNC; 59% greater than the US rate (2008). Although the rate for ENC is decreasing by 5% over 1999-2008, the HP 2010 target of 9.2 deaths per 100,000 will not be met soon.
- 10-year trends for males and White females are unreliable though rates are continually higher in men, both White and non-White. The non-White female mortality rate has decreased 40% over the 10-year period and is projected to meet the HP 2010 goal.
- The non-White rates have decreased by 16% over the 10-year period and converged with the White rates suggesting a reversal in disparity within ENC.
Recent observed rates and fitted rates suggest that the racial disparity in ENC may already be eliminated, and may actually favor non-Whites. With a moderately reliable 10-year trend, the racial disparity has decreased 127%.

**Nephritis, Nephrotic Syndrome, and Nephrosis**
- Mortality due to nephritis, nephrotic syndrome, and nephrosis in ENC has increased by 31% over 10 years, a rate divergent from those of RNC and NC. While other regions have also experienced large increases during this time period, ENC rates are diverging, 16% greater than RNC in 2008.
- With age-adjustment, ENC has increased by 19% over the 10-year period, similar to the 20% rate increase for RNC.
- The 10 year trends for non-White males and females are unreliable but continually above those for White males and females. The demographic group with the greatest rate of increase is White males, increasing 40% over 10 years.
- In 2008, the non-White rate was 119% greater than the White rate. In 1999 the non-White rate was 163% greater than the White rate.
- A moderately reliable trend shows a 30% decrease in racial disparity over the 10-year period.

**Cancer – Colon, Rectum, Anus**
- The cancer – CRA mortality rates are decreasing for ENC, RNC, and NC but the 10-year trend for ENC is diverging from RNC and NC. In 2008, the ENC rate was 7% greater than the RNC rate.
- The age-adjusted mortality rate for ENC is decreasing at a similar rate to RNC, NC, and US (22% over 10 years).
- All demographic groups show a decrease in mortality rates, with the greatest rate of decline for White males (a 29% decrease in 10 years). Non-White males continue to have the highest rates of all demographic groups.
- The non-White and White mortality rates are decreasing by 18% and 25% respectively, and are diverging. In 2008, the non-White rate was 41% greater than the White rate.
- The 10-year increasing trend for racial disparity is unreliable.

**Cancer – All Sites**
- The cancer – all sites mortality rates for ENC have decreased slightly (3%) over 10 years. The RNC and NC rates have decreased more than ENC, causing these rates to diverge.
- The age-adjusted cancer – all sites mortality rates for ENC, NC and RNC are all decreasing at about the same level. The age-adjusted rates are not diverging.
- The rates for non-White males have decreased 24% over 10 years, and are projected to converge with the rates for White males, which show a 16% decrease. The rates for White females and non-White females are flat.
- Both White and non-White cancer mortality trends are decreasing over the 10 year period. Non-White rates decreased 14% and White rates decreased 10%, suggesting future convergence.
- The decreasing trend for racial disparity is not reliable.

**HIV Disease**
- For the period 1999-2008, the fitted HIV mortality rates for ENC have been decreasing, but are still 40% greater than RNC in 2008.
- The age-adjusted rate of decrease for ENC HIV mortality for the period 1999-2008 is the least of all the NC regions with a 29% decrease. The greatest decreasing trend during this time period was experienced by RNC59, a 43% reduction between 1999 and 2008.
- Non-White males continue to have the highest rates of age-adjusted mortality, but these rates have also decreased 30% in a reliable trend during 1999-2008. White males, over the same period experienced a decrease of 25% and non-White females experienced a decrease of 24%. The decrease for White females is misleading because the absolute rate for this group is low.
- From 1999 to 2008, non-White age-adjusted HIV mortality rates have decreased by 28% in a reliable trend. Age-adjusted mortality rates for Whites decreased by 34%, although the absolute rate for this group is much lower.
- Racial disparity increased 17% over the 1999-2008 time period.
3. Methods, Interpretation, and References

Data Sources
The data for mortality and premature mortality in Eastern North Carolina were obtained from death certificate data from the North Carolina State Center for Health Statistics and population data from the North Carolina Office of State Planning. For the US, data were obtained from the Compressed Mortality File compiled by the National Center for Health Statistics.

Measures
Two types of mortality measures are covered in this report. The first, called mortality rate, is a rate based on the number of deaths per population (or, deaths normalized by the population that produced them) for a given unit area, such as the county, region, or state over a specified time interval. The mortality rate is expressed in two ways, the basic true (actual or observed) rate, and an age-adjusted rate (see below). Mortality rates are used to evaluate the impact and burden of mortality on a population and to make comparisons, where appropriate, among populations. Like the mortality rate, the second type, called premature mortality rate, is also a density measure, but instead of deaths, it is the number of person-years lost in a population before a specified age. In this report mortality rates are emphasized with premature mortality (YLL-75) shown only for the total number of deaths from all causes (general mortality). Premature mortality in detail is the focus of Report Series #1.

A simple count of deaths occurring in an area for a given time interval is useful for identifying potential problems or issues of public concern—particularly if the deaths result from a rare cause or they are believed to be an emerging problem for at-risk socio-demographic groups. In this sense, count data are used for sentinel surveillance. Because counts reveal nothing about the underlying population base from which deaths arise, the analytical or practical utility of count data is limited. The size of the underlying population will have an expected effect on the numbers of deaths that occur. Deaths measured in relation to a population, are an expression of density. When measured over a given interval of time (usually 1 to 5 years), the density is called a rate. (The rate is typically multiplied by 100,000 for ease in interpreting the usually small resultant value.) The mortality rate is an improvement over simple count data because it accounts for the relative size and effect of the underlying population. The chief advantage of the mortality rate is that it is useful for focusing attention on the burden of public health problems more rigorously than simple counts. However, the mortality rate is also affected by the age structure of the population, which can confound interpretation when making comparisons of rates among different areas.

Because aging is the greatest risk factor for death, the age structure of a population will have a substantial effect on the mortality rate. For example, two counties may have similar population sizes but one has a larger number of people over the age of 45 than the other. It is more likely that the older population will generate more deaths over an interval of time and this will be reflected in a higher mortality rate. Differing age structures among populations will confound any comparisons of mortality rates among those populations. Therefore, a method for controlling the effects of age structure on the mortality rate is required if any meaningful comparisons are to be made.

Age-adjustment to control for a population’s age structure requires an external reference or standard to weight the comparison populations by age groups. Currently, the US 2000 Standard Million Population (SMP) is used as the external reference. The US 2000 SMP is divided into a number of age groups whose sizes or proportions serve as weights to be applied to the corresponding age groups of the study population. This proportional redistribution generates new numbers of expected deaths in each of the corresponding age groups of the study population. These expected deaths are the number of deaths we would expect if the study population had the same age structure as the US 2000 SMP. The
expected number of deaths are summed and normalized by the total population yielding an age-adjusted death rate. Once the effects of age structure are controlled, the way is paved for making comparisons among populations (Buescher, 1998).

The second measure, premature mortality, focuses on the burden of disease and death expressed in terms of accumulated person years lost before a benchmark age. We use 75 years of age as a benchmark because it approximates current life expectancy at birth in the United States and gives weight to deaths from chronic disease occurring in later life. It considers only deaths of people who die before age 75. To calculate the number of years lost, the mid-point age of the age group to which each decedent belongs is subtracted from 75 and the differences (the lost years) are summed. After all lost years are summed; the result is normalized by the population under age 75 and multiplied by 10,000. Premature mortality is expressed as a rate measured over a time interval, and it can also be age-adjusted.

Age-adjusted rates for both mortality and premature mortality have little intrinsic meaning, however, and can mask the burden and trends of mortality (or health event) that may be of local importance. A casual inspection of adjusted rates may divert attention from the actual health problems of a population and inappropriately guide interventions or resource allocation. Thus, it is important to consider the actual number of deaths (count data) in conjunction with the basic non-adjusted mortality rate first, and then use the adjusted rate only if one wishes to factor out age in understanding the pattern of mortality among populations and regions. For regions with larger populations the statistics presented here are for the year 2008. Smaller areas like counties will usually be aggregated into 5-year intervals (e.g., 2003 to 2007). A five-year interval is used because it provides a useful summary of the mortality experience while minimizing wide year-to-year fluctuations in the rate due to the effect of small numbers.

Interpreting the Pie Charts
Pie charts are provided as a visual representation of the burden of mortality. They depict the proportion of mortality accounted for by each of the leading contributors. (The leading causes of death are found in the table preceding the pie chart section.) The pie charts compare the relative levels of burden and proportions by region and demographic groups. Each regional and demographic set of pie charts is based on the observed mortality rate and the age-adjusted (expected) mortality rate. The area of each pie is based on the age-adjusted mortality rate for the year 2008--larger pie charts will represent larger mortality rates. For purposes of presentation, we set the smallest area of a circle on the lowest meaningful rate as a benchmark, the age-adjusted rate for White females in North Carolina. We then scaled up the circles for all other groups proportionately based on their rates.

The first two pie chart figures compare the proportions of leading causes of death across regions at the national, state, and regional/county level. The first figure in this set compares absolute mortality (the burden) using mortality rates, which sheds light on any differences in the burden of mortality by disease intrinsic to each region. The second figure, which is age-adjusted, allows for direct comparisons among regions. The same pattern is repeated in the following figures that show differences among demographic groups.

While comparing the pie charts, the reader should remember that the slices of the pie show differences in how much of the mortality rate (including age-adjusted) is accounted for by a specific cause. Finally, the reader will see that some pies are composed of different leading causes of mortality, so they have different colored slices. The variable sizes of pie slices demonstrate differences in the mortality patterns across populations and are of significant importance in studying inequalities and disparities in population health.
Interpreting the Trend Figures

Four types of figures are used to show trends in mortality, for all causes combined, and for each of the ten leading causes in the region/county over a 29-year period. Premature mortality is described for deaths by all causes only. The first of the four types of figures depicts the observed mortality rates for the region/county and state. The second figure type shows age-adjusted mortality rates for the region/county, state, and nation allowing comparisons among geographical areas. The third figure type compares trends in age-adjusted mortality rates by race and gender. Adjustment is made for age structure differences among demographic groups, which permits observation on the effects of race and gender on these groups. The last figure type depicts racial differences (or disparities) expressed as a ratio (in percent) of age-adjusted mortality for non-Whites to the age-adjusted rates for Whites over the 29 year time series. Trend lines provide historical depth to mortality processes and a basis for prediction, future comparisons, and action.

The trend line concept is borrowed from statistical modeling. However, unlike true modeling, we are not assuming the statistical independence of each sequential observation (the rate at time interval x). Instead, our assumption is that each observation is dependent to some degree on previous observations, forming a trend. If the degree of dependence is high, then the observations (rates) should lie close to the trend line. If observations appear to bounce around the fitted line in a random fashion (indicating high variability), then there is less dependence and less of a trend in the observations. We use trend lines to uncover any general patterns found in the data for the purpose of assisting the investigator in understanding the underlying processes which generate them.

The equation of the line is derived from a set of observation points. This line is an estimate of where each observed rate would be if the previous observation could predict with 100% accuracy the value of the next observation. In nature, this situation seldom arises and the degree to which individual observations deviate from this linear trend line is an indication of how well they “fit” or conform to the trend. The linear trend lines in the time series figures project expected rates to the year 2020 from known historical values (1979 to 2008) to provide a general idea about where mortality trends are heading.

The equation of the line allows the user to calculate an expected or fitted rate for any given year, x. For example, in figure 6.4 ii the year 1990 is the 12th year in the series, so 12 would be substituted for x in the equation of the line derived from ENC41’s age-adjusted mortality rate series for a selected cause of death. For chronic lower respiratory diseases (1979 to 2008), the 1990 expected or fitted age-adjusted rate is calculated to be a little more than 36 deaths per 100,000 people. The observed age-adjusted rate for 1990 is 38 deaths per 100,000 people. (The observed rates are the values found in the table that runs along the x-axis of the time series chart.) The numeric difference between the expected and observed rates for 1990 is 2—the model (the equation of the line) underestimates the observed value by 2 deaths. Each previous and subsequent year’s difference between the expected and observed rates will vary to a greater or lesser degree depending on the size of the population under study (see below). This variation can be measured to determine how well the line fits or models the observed data.

In the time series figures, the investigator will find several statistical tools to assist in the analyses of trend lines and fitted rates. These tools include the coefficient of determination, percent change values, and slope coefficients. These tools enable the investigator to form not only a mental picture of the comparative impact of mortality by cause on a region and population but to also gain insight into what the near demographic future holds for them.

Coefficients of determination ($R^2$) are provided to indicate how well the fitted line predicts or explains the observed rates. When variation in the observed rates is relatively high (the fitted trend line does not correspond well to the observed trend line) $R^2$ approaches 0.0, when the variation
is low, \( R^2 \) approaches 1.0. A low \( R^2 \) implies low reliability and a larger \( R^2 \) indicates that a greater degree of confidence can be placed in the trend line. The trend lines are generally unreliable when \( R^2 \) is less than 0.10, moderately reliable when \( R^2 \) is between 0.10 and 0.35, and most reliable when \( R^2 \) is equal to or greater than 0.35. Graphically, data points, data lines and trend lines are weighted according to their reliability and significance. The thinnest, dashed trend lines are for those where \( R^2 \) is less than 0.10 and should be considered not reliable. The thickest dotted lines are used for trends where the \( R^2 \) is equal to or greater than 0.35. In some cases, the trend lines do not fit the data well (i.e. small \( R^2 \)). In other words, the presentation of a trend line does not necessarily indicate a linear trend in the data line. In several instances a non-linear trend may be present. It should be noted that the linear trend modeling undertaken here is a major simplification of real world processes. These processes are dynamical in nature and can be modeled and fitted with certain limitations and assumptions. Time series of epidemic infectious disease mortality rates typically exhibit a curvilinear pattern. A marked curvilinear pattern is seen in the mortality series for HIV/AIDS mortality, general cancer mortality, and several others which can be approximated into at least two sequential linear segments. Each segment is joined to another in the sequence at a point in time or year. In this series (#2), we begin to explore alternative methods for examining trends that show discontinuities and reversals within the set of time series observations, particularly within the mortality time series for HIV/AIDS.

Percent change provides a measure of the estimated change in mortality over the most recent ten year period (1999-2008). The percent value is followed by the term increase or decrease to help denote the direction of the overall trend. This information is in boldface and included with the \( R^2 \) value and the equation of the line. Percent change and the direction of that change is provided on the graphs for trends where \( R^2 \) is greater than 0.10.

Another tool is the equation of the line that fits a trend among the observed data point (the rates). The slope coefficient of this equation, \( b \), is the estimated/expected number of deaths per unit of time (\( x \)) or the rate of change in deaths per annum. The direction of change is indicated with a negative sign preceding the \( b \) and if positive, \( b \) is unsigned. Visually, a negative slope shows a trend decreasing in annual rates from left to right and a positive slope will be rising (increasing) from left to right. An examination of the different slopes for regional or demographic group trends will quickly reveal that they are not equal. Visual inspection combined with slope coefficients also provides a means for making comparisons between any two trend line series in the time series figure. Trends will diverge, converge, or run parallel with one another indicating, respectively, increasing separation, decreasing separation, or very little change in rates between two trend lines. Setting two equations of the line equal to one another can yield an estimated year of convergence in the future (or the year the two trends diverged in the past). However, the investigator is cautioned to not put too much stock in the results if the forward or backward projections are very distant in time, especially when \( R^2 \) is low. Recent (or temporally adjacent) short term trends with good correspondence between the fitted trend line and observed trend line will be better indicators of rates in the near future or past (if historical rates are unknown).

The final tool is the pair of comparison tables located in the lower portion of the page. The tables, found in every time series figure (except the ones showing comparisons by race and disparity) are structured so that the reader can make comparisons of rates derived from the equation of the line (i.e., the fitted rates) among all regions or demographic groups portrayed in the figure. The 1999 and 2008 tables compare the fitted rates calculated for the beginning and end of the observed time series in terms of percent difference. Returning to figure 6.4 ii, ENC41’s age-adjusted fitted rate for chronic lower respiratory diseases in 1999 is 10% greater than (GT) RNC’s fitted rate. In 2008, ENC41’s fitted rate is 5% less than (LT) RNC’s fitted rate. The tables permit a quick assessment of trends calculated from observed time series data.

The reader should notice that some data lines in the trend figures fluctuate widely. This fluctuation is due to two main factors. In a small population, the number of deaths may vary widely from year-to-year and lead to large changes in annual mortality and premature mortality rates, a phenomenon known as the effect of small numbers. In addition, because mortality is based on the age of death, any fluctuation in the
distribution of deaths across age groups from year-to-year can cause rates to change dramatically. Both the number of deaths and the age of decedents influence trends in mortality. The reader should evaluate all available data carefully before drawing conclusions about current, past and future mortality patterns.

Caveats about the Concepts of Race, Gender, and Geography

Several caveats are offered about the concepts of race, gender, and geography as they apply to the analysis of mortality patterns. While we do intend to bring attention to the stark racial inequalities in mortality across North Carolina, we do not mean to imply that this is a biological phenomenon. Other factors such as differences in socioeconomic status, educational attainment, occupation, and lifestyle probably account for the large racial gaps in mortality rates. Likewise, gender inequalities may have less to do with biological differences between men and women than with socially structured gender roles, health behaviors, occupational exposures, and use of health services. Finally, it is important to consider that county borders may not always be the most appropriate way to look at specific health problems. Few of our health care problems begin or end at political boundary lines and many of our health problems in North Carolina are common to large groups of counties. Counties and larger regions composed of counties are convenient units of data collection and readers should not jump to conclusions about health problems or possible solutions based solely on the way data appear when aggregated to this level. In some cases, data at multi-county, zip code, or minor civil division levels are a better way to understand problems and solutions. Similarly, as indicated in Healthy Carolinians 2020, consideration needs to be given to whether or not a county is characterized as rural or urban, as this can be an indication to the level of development and amount of resources available in a county.

5. Trends and Disparities in Mortality in ENC41:
   All Causes of Death and All Causes of Premature Mortality;
   1979-2008
All Causes of Death

- ENC’s all-cause mortality rates are increasing and diverging from RNC and NC over the 30-year trend. Over the 10 year trend period, however, ENC, NC, and RNC are decreasing. ENC is not decreasing as quickly as NC and RNC.

- The age-adjusted, all-cause mortality rates for ENC are decreasing over the 30 year period. Over the 10 year period, the trend shows greater decrease, and suggests the ENC rate will converge with the RNC and NC rates. ENC’s rate continues to remain 10% greater than the rate for RNC.

- The non-White male mortality rates remain higher than the other demographic groups but have had the greatest rate of decrease (23%) in the 10-year trend. Convergence of non-White males with White males is suggested in the future.

- The trends for all-cause mortality rates for both non-Whites and Whites are decreasing. The non-White rate is 19% greater than the White rate, but the recent 10 year trend suggests they will converge.

- There is a 45% increase in racial disparity over the 30 year period. Over the recent 10 year period, however, there is a sharp drop in racial disparity, in a moderately reliable trend.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$. 
Figure 5.1 i. All Causes of Death: Trends in mortality rates for ENC41, RNC59, and NC 1979-2008 with projections to 2020

ENC41 10-yr trendline 7% decrease
R2 = 0.78
y = -6.39x + 935.99

RNC59 10-yr trendline 10% decrease
R2 = 0.72
y = -9.31x + 899.93

NC 10-yr trendline 9% decrease
R2 = 0.74
y = -8.54x + 910.85

1999 ENC41 rate is 4% greater than RNC59
2008 ENC41 rate is 8% greater than RNC59

Racial Disparity
31% decrease
R² = 0.27
y = -0.84x + 26.57
All Causes of Premature Mortality

- ENC’s premature mortality rate has decreased by 5% over the 10 year period since 1999. However, this trend is diverging slightly from both RNC and NC, whose premature mortality rates decreased by 8% and 7%, respectively.

- The age-adjusted premature mortality rate trend is also decreasing, but remains 23% higher than the RNC rate in 2008.

- The non-White male rates are significantly higher than any other demographic group, but also have the highest rate of decrease (slope of trend). White females have the lowest rate and also the lowest rate of decrease.

- The non-White female fitted rate was 77% greater than that of the White females in 1999, decreasing to 60% greater in 2008.

- A recent decrease in the premature mortality rate for non-White males and leveling of rates for White males suggests a reduction in racial disparity.

- The non-White rate remains about 59% greater than the White rate.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$. 
Figure 5.2 i. All Causes of Premature Mortality:

Racial Disparity
24% decrease
R² = 0.39
y = -1.65x + 69.66
Diseases of Heart

- ENC’s heart disease mortality rate trend is decreasing but not as quickly as the decrease for RNC and NC, resulting in an increased geographic disparity. In 1999 it was 7% less than RNC; by 2008 it was 15% greater than RNC.

- While ENC’s age-adjusted mortality rate is decreasing at a pace equal to RNC, the ENC rate remains 18% greater than RNC in 2008.

- The non-White male rates remain the highest but convergence with White males is suggested in the future. The non-White female rates remain slightly higher than the White females but are decreasing at a higher rate and suggested to fall below White females in the future.

- While non-White rates remain 13% greater than for Whites, the 10-year trends are both decreasing and convergence is suggested in the future.

- The 30-year trend suggests an increase in racial disparity after an initial reversal of disparity that favored non-Whites. The 10-year trend line for racial disparity is unreliable.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

1999 non-White rate is 15% greater than White
2008 non-White rate is 13% greater than White
Figure 6.1 v. Diseases of Heart:
Measuring disparity in age-adjusted mortality rates by race for ENC41, 1979-2008 with projections to 2020

Racial Disparity

R² = 0.01
y = -0.15x + 14.84
Cancer - Trachea, Bronchus, Lung

- While the 30-year trends for Cancer—TBL indicate that all mortality rates are continuing to increase, the 10-year trend line suggest a slight decrease in all three trends. However, ENC continues to be 9% greater than RNC in 2008 and has divergence from RNC and NC.

- In 2008, the age-adjusted rate for ENC is 8% above the RNC rate and 18% above the US rate. During the period 1999-2008, the ENC rates are decreasing at a greater rate, suggesting convergence with RNC and NC in the future.

- The mortality rates for males are decreasing as female rates are increasing. While the non-White male rate remains the highest, it is decreasing at the quickest rate (28%) and is expected to fall below White males.

- The non-White mortality rate (combined males and females) for this cancer is consistently lower than the white rate. Both rates are decreasing over the 10 year period, but the non-White rate is decreasing more quickly.

- The decreasing trend for racial disparity is not reliable.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

1999 non-White rate is 8% less than White
2008 non-White rate is 13% less than White
Figure 6.2 v. Cancer - Trachea, Bronchus, Lung: Measuring disparity in age-adjusted mortality rates by race for ENC41, 1979-2008 with projections to 2020

Racial Disparity

\[ R^2 = 0.07 \]
\[ y = -0.76x - 9.13 \]
Cerebrovascular Disease

- ENC’s cerebrovascular disease mortality trend line is decreasing and diverging slightly from RNC and NC. In 1999, the ENC rate was 2% greater than RNC compared to 6% greater in 2008.

- While the ENC age-adjusted cerebrovascular disease mortality rate is 9% greater than the rate for the rest of the state, it is decreasing and converging on the RNC and NC rates. Projected to 2010, the Healthy People 2010 goal of less than 48 deaths per 100,000 could be achieved in the region.

- Non-Whites have the highest mortality rate for cerebrovascular disease but the rate continues to decrease and converge with the other demographic groups. The greatest relative improvement in cerebrovascular disease mortality over 10 years is by White males who experienced a 51% decrease. The non-White male rate in 2008 is 75% greater than the rate for White males; the non-White female rate is 43% greater than the rate for White females.

- The cerebrovascular disease mortality rate for non-Whites is decreasing and converging with that of whites but is still 52% greater than Whites in 2008.

- The moderately reliable 10-year trend for racial disparity shows a 46% increase

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

Figure 6.3 v. Cerebrovascular Disease: Measuring disparity in age-adjusted mortality rates by race for ENC41, 1979-2008 with projections to 2020

Racial Disparity
46% increase
R² = 0.26
y = 1.66x + 36.14
Chronic Lower Respiratory Diseases

- The CLRD mortality rates for ENC are slightly lower than the rates for RNC and NC in 2008, with all 3 trends increasing. Only RNC has a moderately reliable 10-year trend with a 6% increase.

- The 10-year CLRD age-adjusted rate for ENC is decreasing at a similar rate of decline as the US. In 2008, the ENC rate is 5% less than RNC compared to 1999 when the ENC rate was 10% greater than RNC.

- Fitted rates for non-White male and White male mortality have decreased over 10 years by 39% and 22%, respectively. White male rates remain the highest and although decreasing, are diverging from non-White males. The 10-year trend for White females show a 7% increase and the trend for non-White females is unreliable.

- The 10-year White morality rates are greater than non-White rates and the rate of decline is less for Whites, leading to a divergence more favorable to non-Whites.

- There is a 70% decrease in the disparity between White rates and non-White rates in a reliable trend.

Unless otherwise noted, trends are considered reliable if \( R^2 \geq 0.35 \), moderately reliable if \( 0.35 > R^2 \geq 0.10 \), and unreliable if \( R^2 < 0.10 \).

Diabetes Mellitus

- According to the 10-year trend, all diabetes mellitus mortality rates are decreasing but the rate of decline is less for ENC suggesting a divergence from RNC and NC. In 2008, the rate for ENC is 41% greater than RNC. In 1999 ENC was 26% greater than RNC.

- The 10-year trend for age-adjusted diabetes mellitus mortality rates shows a decrease of 13% for ENC as the rates for RNC and NC have fallen below the US rate. In 2008, the ENC age-adjusted diabetes mellitus death rate remains 43% greater than the RNC and 12% greater than the US rate.

- The non-White male and non-White female 10-year mortality rate trends are decreasing and converging with those of White males and White females. The annual decrease for the highest group, non-White males, is 2.0%.

- Non-White mortality rates decreased over 10 years by 17% but remains 131% greater than Whites in 2008.

- There has been a 14% decrease in racial disparity from 1999-2008. The trend in disparity is decreasing at an average of 1.4% per year, with a moderately reliable trend.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

All Other Unintentional Injuries and Adverse Effects

- Mortality from unintentional injuries and adverse effects is increasing in ENC (37% increase over 10 years). The trends for RNC and NC are also increasing, more quickly than ENC.

- The age-adjusted mortality rates for ENC, RNC and NC are also increasing. The rate of increase is higher for NC and RNC than for ENC, but all three increased 30% or more over 10 years.

- 10 year trends for White males and White females are increasing significantly (40% increase for White males, 87% increase for White females). Mortality rates for non-White males decreased 21% over 10 years, and the trend for non-White females is relatively flat.

- White rates have increased 56% over the 10 year period. Non-White rates have dropped below white rates, and are decreasing, in an unreliable trend.

- Between 1999 and 2008, the racial disparity has decreased by 295%, eliminating the unfavorable disparity in relation to whites.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

Racial Disparity

295% decrease
R2 = 0.52
y = -6.75x + 22.93
The Alzheimer’s mortality rate for ENC shows a 72% increase over the 10 year period. ENC’s rate of increase was larger than RNC and NC but the rate for ENC still remains 37% less than RNC.

In 2008, the age-adjusted rate for ENC is 13% below the US rate with a rate of increase comparably similar to both the NC and US rates.

The mortality rate for females, both White and non-White, is greater than that of non-White and White males in an increasingly divergent 10-year trend.

The non-White mortality rate for Alzheimer’s remains 10% less than the White mortality rate in 2008 but the 10-year trend suggest convergence in the near future.

The 10-year trend suggests an increase in disparity that is beginning to favor whites.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

1979-2008 with projections to 2020

Racial Disparity
72% increase
R² = 0.22
y = 2.58x - 36.05
Unintentional Motor Vehicle Injuries

- ENC’s unintentional motor vehicle injury mortality rate is decreasing but is 49% greater than RNC in 2008. Because of its smaller rate of decrease, ENC rates are diverging from the RNC and NC rates.

- The ENC age-adjusted rate is 49% greater than RNC; 59% greater than the US rate (2008). Although the rate for ENC is decreasing by 5% over 1999-2008, the HP 2010 target of 9.2 deaths per 100,000 will not be met soon.

- 10-year trends for males and White females are unreliable though rates are continually higher in men, both White and non-White. The non-White female mortality rate has decreased 40% over the 10-year period and is projected to meet the HP 2010 goal.

- The non-White rates have decreased by 16% over the 10-year period and converged with the White rates suggesting a reversal in disparity within ENC.

- Recent observed rates and fitted rates suggest that the racial disparity in ENC may already be eliminated, and may actually favor non-Whites. With a moderately reliable 10-year trend, the racial disparity has decreased 127%.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

Racial Disparity
127% decrease
R2 = 0.16
y = -1.96x + 15.45
Mortality due to nephritis, nephrotic syndrome, and nephrosis in ENC has increased by 31% over 10 years, a rate divergent from those of RNC and NC. While other regions have also experienced large increases during this time period, ENC rates are diverging, 16% greater than RNC in 2008.

With age-adjustment, ENC has increased by 19% over the 10-year period, similar to the 20% rate increase for RNC.

The 10 year trends for non-White males and females are unreliable but continually above those for White males and females. The demographic group with the greatest rate of increase is White males, increasing 40% over 10 years.

In 2008, the non-White rate was 119% greater than the White rate. In 1999 the non-White rate was 163% greater than the White rate.

A moderately reliable trend shows a 30% decrease in racial disparity over the 10-year period.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

Cancer - Colon, Rectum, Anus

- The cancer – CRA mortality rates are decreasing for ENC, RNC, and NC but the 10-year trend for ENC is diverging from RNC and NC. In 2008, the ENC rate was 7% greater than the RNC rate.

- The age-adjusted mortality rate for ENC is decreasing at a similar rate to RNC, NC, and US (22% over 10 years).

- All demographic groups show a decrease in mortality rates, with the greatest rate of decline for White males (a 29% decrease in 10 years). Non-White males continue to have the highest rates of all demographic groups.

- The non-White and White mortality rates are decreasing by 18% and 25% respectively, and are diverging. In 2008, the non-White rate was 41% greater than the White rate.

- The 10-year increasing trend for racial disparity is unreliable.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

7. Trends and Disparities in Mortality in ENC41: Cancer - All Sites and HIV Disease; 1979-2008
Cancer - All Sites

- The cancer – all sites mortality rates for ENC have decreased slightly (3%) over 10 years. The RNC and NC rates have decreased more than ENC, causing these rates to diverge.

- The age-adjusted cancer – all sites mortality rates for ENC, NC and RNC are all decreasing at about the same level. The age-adjusted rates are not diverging.

- The rates for non-White males have decreased 24% over 10 years, and are projected to converge with the rates for White males, which show a 16% decrease. The rates for White females and non-White females are flat.

- Both White and non-White cancer mortality trends are decreasing over the 10 year period. Non-White rates decreased 14% and White rates decreased 10%, suggesting future convergence.

- The decreasing trend for racial disparity is not reliable.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.

Racial Disparity

R2 = 0.07
y = -0.57x + 19.14
HIV Disease

- For the period 1999-2008, the fitted HIV mortality rates for ENC have been decreasing, but are still 40% greater than RNC in 2008.

- The age-adjusted rate of decrease for ENC HIV mortality for the period 1999-2008 is the least of all the NC regions with a 29% decrease. The greatest decreasing trend during this time period was experienced by RNC59, a 43% reduction between 1999 and 2008.

- Non-White males continue to have the highest rates of age-adjusted mortality, but these rates have also decreased 30% in a reliable trend during 1999-2008. White males, over the same period experienced a decrease of 25% and non-White females experienced a decrease of 24%. The decrease for White females is misleading because the absolute rate for this group is low.

- From 1999 to 2008, non-White age-adjusted HIV mortality rates have decreased by 28% in a reliable trend. Age-adjusted mortality rates for Whites decreased by 34%, although the absolute rate for this group is much lower.

- Racial disparity increased 17% over the 1999-2008 time period.

Unless otherwise noted, trends are considered reliable if $R^2 \geq 0.35$, moderately reliable if $0.35 > R^2 \geq 0.10$, and unreliable if $R^2 < 0.10$.
